Bullous pemphigoid mimicking toxic epidermal necrolysis[☆]

Dear Editor,

Bullous pemphigoid (BP) is a well-known condition triggered by autoantibodies directed against hemidesmosomal proteins involved in the adhesion of basal keratinocytes to the basement membrane. Diagnosis is established by detection of subepidermal bullae with an eosinophil-rich infiltrate on histopathology and the identification of antibodies against the basement membrane zone (BMZ) using direct and or indirect immunofluorescence.¹

In addition to the classic presentation with disseminated tense bullae, numerous variants of BP are recognized, such as pruriginous, erythrodermic, urticarial, and also those mimicking toxic epidermal necrolysis (TEN)¹; the urticarial form is the most frequent among the non-bullous forms.²

A 52-year-old black female patient with no comorbidities one week after using prednisone, ceftriaxone and pantoprazole for pharyngitis, had presented diffuse erythema with desquamation all over the skin (Fig. 1A). The clinical hypothesis of a drug-related eruption was raised. Given the dissemination and intensity of the condition, methyl-

Figure 3 Immunohistochemistry with anti-IgG antibody showing positivity on the floor and roof of the bulla (arrows).

prednisolone 500mg IV was administered for five days. After the intravenous corticosteroid, the patient was maintained on daily oral prednisone 60mg, when small bullae started to appear (Fig. 1B), without mucosal involvement and with mild eosinophilia. On the tenth day, epidermal detachment began to occur, resembling TEN (Fig. 1C and D), there was an increase in the eosinophilia (reaching 3,700 eosinophils/mm³).

As the patient developed fever, intravenous ciprofloxacin was started and prednisone was reduced to 40mg, which led to the appearance of some new bullae. Due to the risk of a new infection, the dose was reduced to 30mg, but with the appearance of new bullae, the 40mg dose was restarted. A bulla was then biopsied and on histopathology subepidermal cleavage, without epithelial necrosis and with significant eosinophilic infiltration in the dermis and inside

the bulla were observed (Fig. 2). The immunohistochemical analysis showed IgG deposition on the floor and roof of the bulla (Fig. 3). Indirect immunofluorescence showed linear positivity for IgG in the BMZ. Over the next ten days, the skin exfoliation worsened. On the twentieth day, there were areas of re-epithelialization, erosions of the initial bullae and new bullae concomitantly (Fig. 4A). The condition was controlled after four weeks of 40mg prednisone (Fig. 4B). Eosinophilia persists and the patient reports significant pruritus, even with the lesions under control.

Mimicking TEN by bullous pemphigoid is known to occur but rare,^{3,4} and the diagnosis can be difficult in the early phase of the disease.⁵ There is also a report of a case triggered by immunotherapy for solid neoplasia.⁶ It is likely that the intense production of antibodies against hemidesmosomal proteins leads to epidermal detachment but without

Figure 4 (A) Re-epithelialized hypochromic areas, erosions resulting from the first worsening episode and new bullae. (B) Almost complete re-epithelialization of the lesions.

epithelial necrosis as in TEN. Other autoimmune diseases that affect the dermo-epidermal junction can also simulate TEN.⁷

Absence of mucosal involvement may suggest TEN. Peripheral eosinophilia, as in the present case, occurs in 50% of the cases⁸ of BP, with tissue eosinophilia being a criterion for the diagnosis, correlating with the severity of the condition.⁹

The present case documents a rare variant of BP, as well as the initial diagnostic difficulty.
